

Sydney Harbour: its diverse biodiversity

Pat A. Hutchings, Shane T. Ah Yong, Michael B. Ashcroft, Mark A. McGrouther and Amanda L. Reid

The Australian Museum, 6 College Street, Sydney NSW 2010

ABSTRACT

All records of crustaceans, molluscs, polychaetes, echinoderms and fishes from Sydney Harbour were extracted from the Australian Museum database, and plotted onto a map of Sydney Harbour that was divided into four regions. Records were analysed according to the number of species, genera and families present and over 3000 species were recorded, approximately double to triple the number of species found in the neighbouring Hawkesbury River, Botany Bay and Port Hacking. We examined the rate of accumulation of records and species over time since the 1860s, which followed a stepwise pattern usually correlated with the research activity of specific curators at the Australian Museum. The high species richness of Sydney Harbour is probably the result of multiple factors including significant tidal flushing and the high diversity of habitats present. Not all parts of the harbour have been well sampled, however, and we highlight areas and habitats that should be prioritised for further biodiversity surveys. An Appendix is provided listing all species in the five groups of animals considered here. The present study highlights the remarkable richness of the Sydney Harbour fauna and provides a consolidated background to guide future management and research, and emphasises the values of museum collections.

Key words: Sydney Harbour; diversity; crustaceans, molluscs, polychaetes, echinoderms, fishes

<http://dx.doi.org/10.7882/AZ.2012.031>

Introduction

Sydney Harbour is a drowned river valley that formed during a rise in sea level approximately 10,000 years ago. The entrance, between North and South Heads (~33°50'S, 151°17'E), is about 3 km wide, with a depth of 30 m. The estuary then opens up into Port Jackson, which is fed by three main branches, the Parramatta and Lane Cove Rivers to the west and Middle Harbour to the north (Figure 1). The estuary is about 30 km long with a surface

area of about 50 km² and a total catchment of 500 km² (Birch and McCready 2009). Most of the harbour (49.7 km²) is under tidal influence (Middleton *et al.* 1997).

The shores of Sydney Harbour are largely developed, with 90% of the catchment urbanised. Sydney is Australia's largest city with a population of 4 million people and all projections indicate it will continue to grow. The original shoreline of Sydney Harbour has been

extensively modified since European settlement, with the development of seawalls, removal of mangroves and salt marshes, and small creeks now lined with concrete, forming storm water drains (Figure 2). As an iconic feature of the city, Sydney Harbour has strong aesthetic values and is heavily used for recreational purposes, such as sailing, swimming and fishing. Land values of waterfront property, especially east of the Harbour Bridge, are among the highest in the world. Commercial fishing has been totally banned from the harbour since 2006 due partly to streamlining of commercial fishery licensing and reported high levels of dioxins (<http://www.dpi.nsw.gov.au/fisheries/recreational/info/Sydney-closure>), although recreational fishing still occurs.

Figure 3. Site of the first marine Biological Station at Camp Cove, circa 1885-1895. The station, a charming colonial cottage, was built on the foreshores of Sydney Harbour in 1881 for Russian scientist and explorer Nikolai Nikolaevich de Miklouho-Maclay to study Australia's marine environment. Built of timber with sandstone foundations, the cottage is typical of the practical colonial architecture of the time. It was located at historic Camp Cove, where the First Fleet rested for a night before landing at Sydney Cove. Miklouho-Maclay worked at the Marine Biological Station for just four years, before returning to Russia where he died in 1888. After the late 1880s until 2001 the cottage was a residence for army officers. Today it is a private residence. Photo: courtesy of the State Library. For more details see <http://www.harbourtrust.gov.au/docs/brochure-marine.pdf>

Thus, it is somewhat surprising that no comprehensive examination of the biodiversity of Sydney Harbour has been undertaken to date, given that Sydney is home to one of the oldest natural history museums in the world (The Australian Museum), five universities and, more recently, the Sydney Institute of Marine Sciences (SIMS). Back in the 1880's

there was a marine station at Camp Cove which was built for the Russian scientist and explorer Nikolai Nikolaevich de Miklouho-Maclay to study Australia's marine environment (Figure 3). Prior to this he had been invited by William John Macleay to live at Elizabeth Bay House and to use its small laboratory. The New South Wales Government provided 300 pounds towards the cost of construction with Nikolai Nikolaevich de Miklouho-Maclay raising the remainder of the money through donations to the station which was built in 1881. This Russian scientist also visited the Australian Museum and we are confident that some specimens collected from this station were subsequently deposited in the Australian Museum.

Sydney Harbour is much less known than other estuaries in Australia such as Port Phillip Bay and Moreton Bay, or overseas estuaries, such as San Francisco Bay and Chesapeake Bay in the USA. To provide a baseline for guiding future management and research, we have examined the Australian Museum databases of fishes and four numerically dominant marine invertebrate groups to begin to document the diversity of Sydney Harbour.

The Australian Museum collections date back to at least 1828. The earliest documented fish record from the harbour is from 1878, but many undated records may be older. Among the molluscs, the earliest records are from 1860, 1882 for crustaceans and 1885 for both polychaetes and echinoderms. Australian Museum staff have actively collected material over the decades from Port Jackson as shown in Figures 4 and 5 (McNeil and Musgrave 1926).

Previous attempts to compile faunal lists of the harbour were undertaken for fishes by Franz Steindachner (1866) and invertebrates by Thomas Whitelegge (1889). Steindachner, of Vienna, dealt with 71 species, describing 21 as new (Saunders 2012), including the Eastern Sea Garfish, *Hyporhamphus australis* and the Eastern Pomfret, *Schuettea scalaripinnis*. Whitelegge was a curator at the Australian Museum and assembled all the known data from the literature and the collections. Relevant here is that he recorded 112 species of echinoderms and while

stating that the other groups were present, he indicated that much work remained to be done on these groups. Thus, the aims of this study are to provide the most up-to-date summary of the harbour fauna. The present study compiles all the Australian Museum records (plus a small number of photographic records) from Sydney Harbour of polychaetes, crustaceans, molluscs, echinoderms and fishes; documents and broadly evaluates the distribution of species within the harbour, and identifies areas of the harbour that have been poorly sampled.

Methods

All Australian Museum database records from the Sydney region of polychaetes, crustaceans, echinoderms, molluscs and fishes were extracted (23 December 2011). Less diverse groups of marine invertebrates, such as sponges, bryozoans and cnidarians, having relatively few collection records, were not included. Geographic Information Systems software (ArcMap; ESRI) was used to select records that were within Sydney Harbour according to the blue polygon in Figure 1a. Many records, especially early ones, have imprecise position data, so including records on surrounding land helped ensure records with low positional accuracy were included. Terrestrial and freshwater species were manually removed as well as those where the collection locality description suggested they were collected close to, but outside of the study area, such as Manly Beach and Shelly Beach, on the ocean side of Manly. In addition, some specific types of records were deleted, such as records for beach-collected dry cuttlebones belonging to deepwater species that probably drifted from some distance offshore and some fossil or sub-fossil molluscs.

Some of the early records only give Port Jackson as the locality; for these records the latitude and longitude values were generalised as a position east of the Harbour Bridge. In some cases, 'Port Jackson' could indicate the specimens were obtained from the Sydney Fish Market and thus may not have been collected from within the harbour, but further afield in the Sydney region; obviously

Figure 4. Bottle and Glass Rocks from McNeill and Musgrave (1926) who quote, 'when the tide is out long lines of rocks lie exposed in the bed of the channel and provide for the marine zoologist one of the richest collecting grounds in Australia'. Photo: Anthony Musgrave, from Australian Museum archives.

Figure 5. Bottle and Glass Rocks from McNeill and Musgrave (1926) who quote, 'The crevices of the outer rocks in the surf zone are encrusted with the hard limy tubes which are the dwellings of the vast numbers of Galeolarian worms'. Photo: Anthony Musgrave, from Australian Museum archives.

this only applies to commercial species. The total number of records, as well as the numbers of families, genera and species was calculated for each of the five taxa (fishes, molluscs, polychaetes, crustaceans and echinoderms) separately and in combination. Not all specimens have been identified to species, and some represent morphospecies or are species currently identified only to a higher taxonomic level. We used WoRMS (<http://www.marinespecies.org/>) to check currently accepted names.

The number of records collected in each year was calculated, with the mean used when a range of dates was given. For example, a record with a stated collection date of 1950–1960, was deemed as 1955. Records without a collection date were counted separately. To display the spatial pattern of records, the study area was divided into a 500 m × 500 m grid, with the number of records in each grid counted and displayed in ArcMap. These analyses were performed to understand the spatial and temporal biases in sampling, and do not necessarily represent the true distribution of biodiversity in the harbour.

Sydney Harbour was divided into four regions: East, Centre, West and North (Figure 1a). We separately counted the number of species in each of the taxonomic groups in each of the four regions. Accumulation curves were produced for each taxon and region based on the earliest record of each species. These accumulation curves

illustrate how the number of species in the Australian Museum collection has grown over time and give an estimate of known species richness in the harbour.

Results

With the exception of molluscs, the majority of records for the selected groups are databased and each of these groups is now discussed. A complete list of species recorded is given in the Appendix. Each species list was checked by one of the authors with expertise in the group. The most recent taxonomic names were used where available but no attempt was made to re-check the database records against specimens. However, every record can be referred back to a specimen, (or, in the case of a few fish records, to a photograph) in our collections. This is the first attempt to collate the fauna of Sydney Harbour since Whitelegge (1889) and hopefully will encourage future studies and re-examination of these museum collections.

Polychaetes

1250 records of polychaetes representing 40 families, comprised of 308 species belonging to 189 genera, with some only identified to genus or in some cases only to family are recorded in the Australian Museum database (Figure 6, Appendix). The families best represented in the Appendix largely reflect the research focus of both

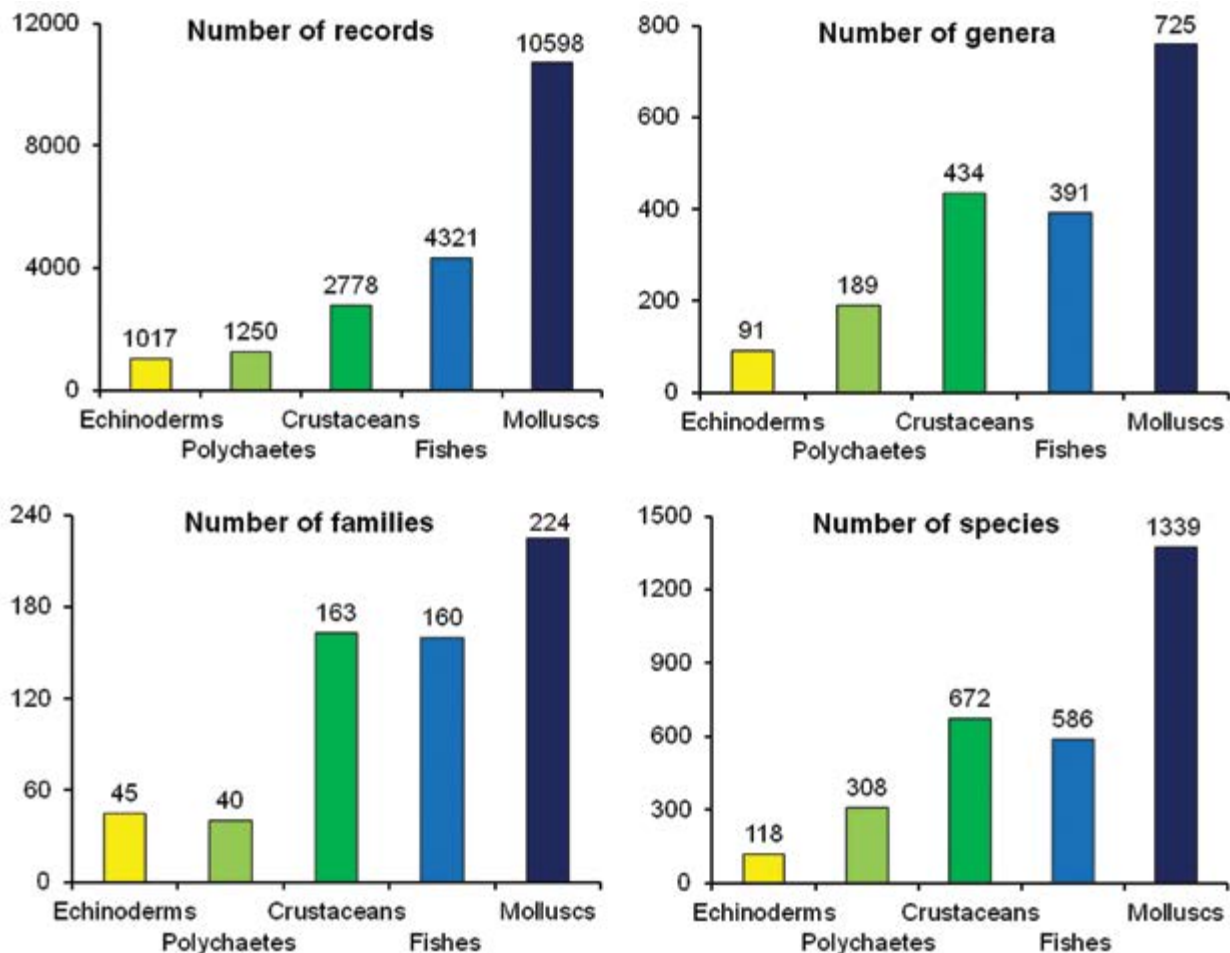

Figure 6. The number of records from the Australian Museum database that were analysed in this study, along with the number of species (including morphospecies), genera and families represented for each group. Taxonomic identifications were based on the database, and were not checked against the actual specimens.

Australian Museum and visiting systematists. Over 80 polychaete families are known globally and currently 40 families are present in the harbour according to the Australian Museum database. However, we know of several other families from the harbour, such as Acoetidae, Magelonidae, Paraonidae and Pisionidae, although specimens of these are yet to be fully identified and databased.

Polychaetes have been recorded throughout the catchment although records from Middle Harbour and Lane Cove are sparse and restricted to the lower reaches (Figure 7). In contrast, records from the Parramatta River are largely restricted to the upper reaches of the river, as a result of various surveys conducted prior to the Sydney Olympics for the Olympic Co-ordinating Agency (Australian Museum Business Services 1993). This is not surprising given that polychaetes are

primarily marine and while the upper reaches of the harbour are fully marine during dry conditions, salinity levels fall in these regions after periods of heavy rain. This probably prevents the establishment of diverse polychaete assemblages, although those species present can be abundant (for example, high numbers were recorded during a bird feeding survey around Homebush Bay (Hutchings 1996)). The bulk of polychaete species are from the East and Central regions (Figure 8), primarily from the shores or shallow water. Few are recorded from deeper water, especially in the Eastern region as little sampling of sediments has occurred there. Many polychaete species occur in sediments and have very specific habitat requirements (Hutchings 1998) so we anticipate additional new species will be recorded based on the range of deeper water sediment types present in the harbour.

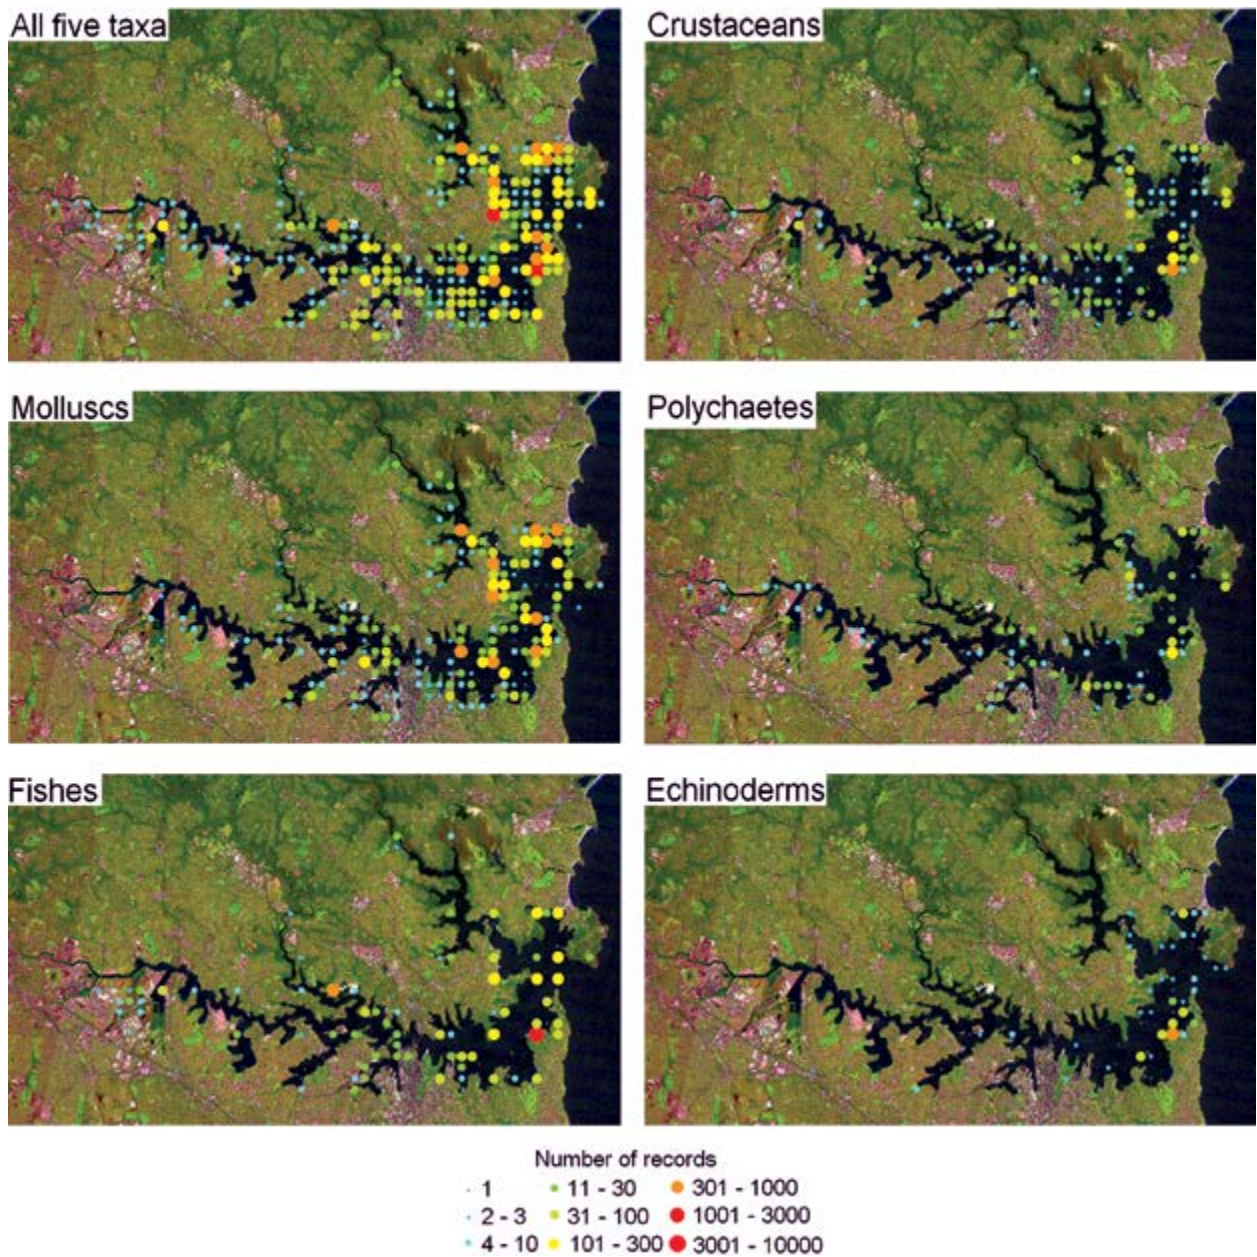

Figure 7. The harbour was divided into a grid of 500 m × 500 m squares. Dots show the number of records in each square. Records vary in collection location precision. In some cases the actual collection locations may differ from those shown on the map.

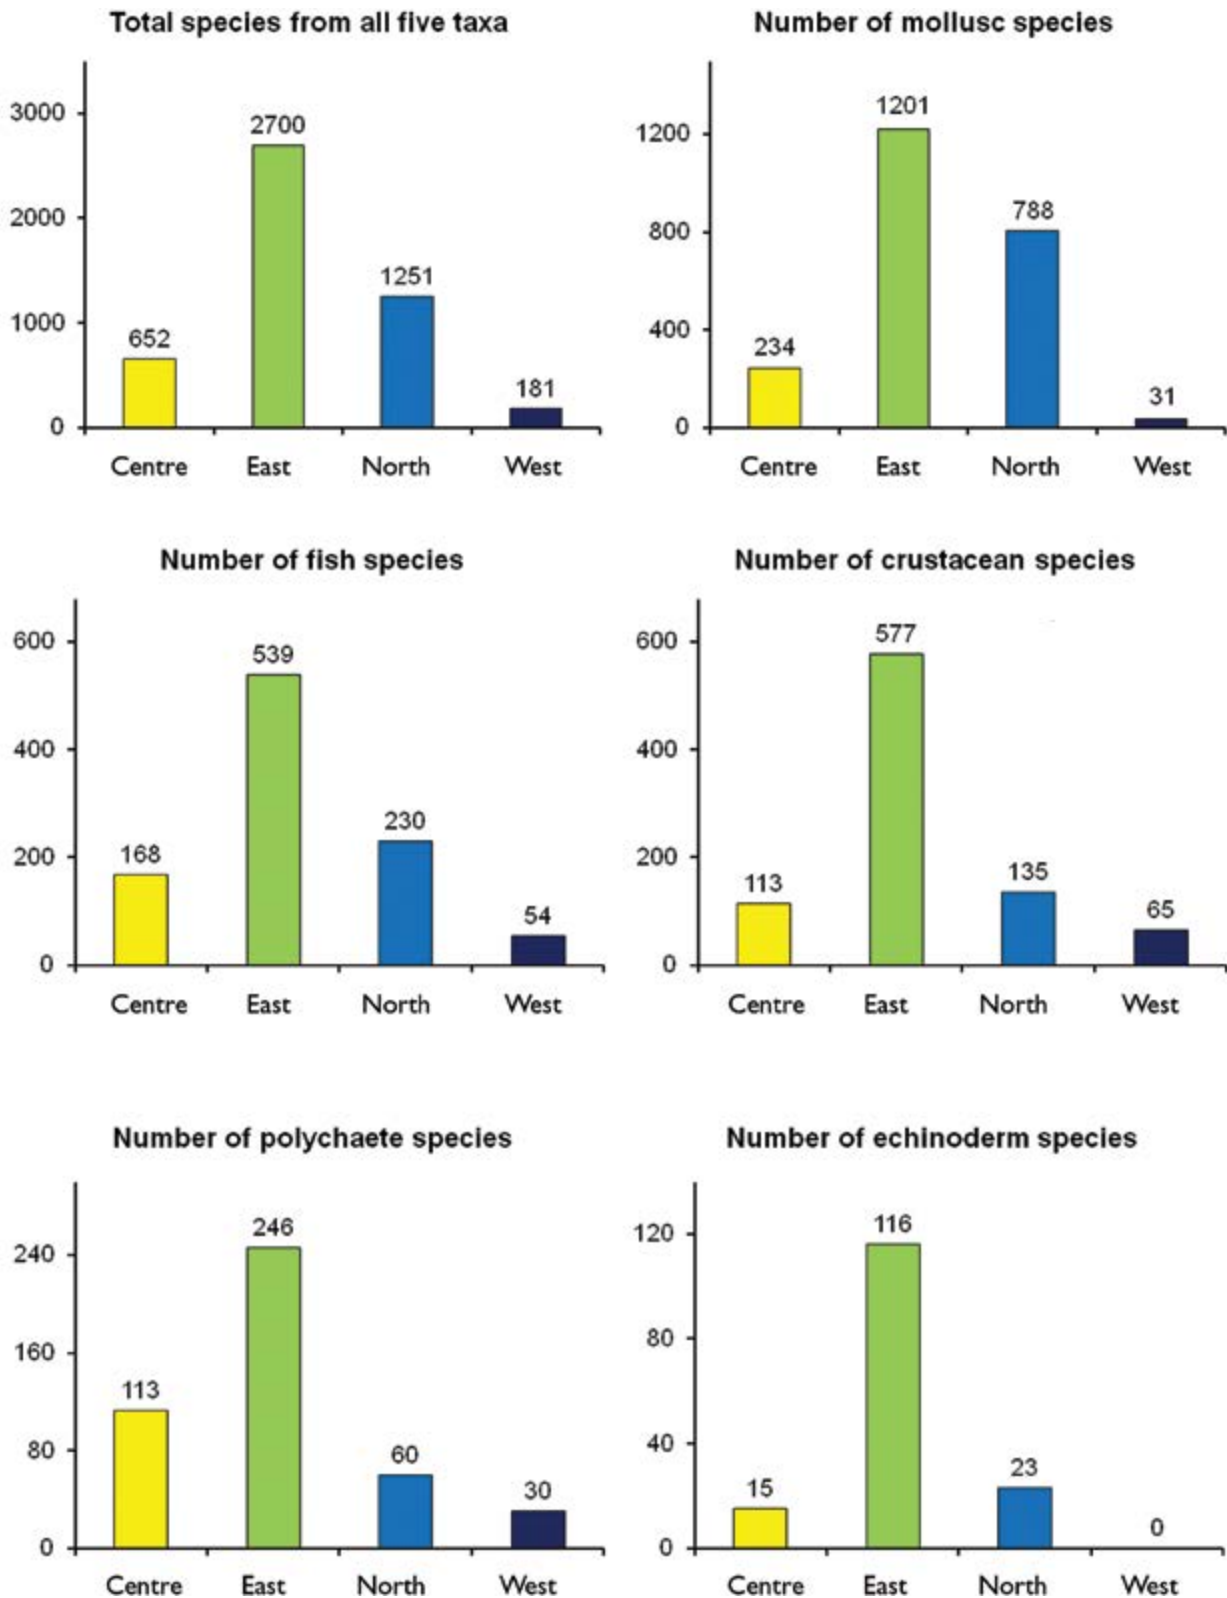

Figure 8. Number of species recorded from each of the four regions of the harbour (Figure 1).

Examination of the time periods when polychaetes were collected (Figure 9) reveals a small peak in the first decade of the twentieth century, followed by very spasmodic collecting until the 1970s. After this, more intensive collecting was undertaken, with a major spike recorded in 2001. This spike is reflected in all other groups and is the result of a major a marine biosecurity survey of

Sydney Harbour undertaken for Sydney Ports Corporation (Australian Museum Business Services 2002) (Figure 10). Another reason for the increasing number of species and records after 1970 was the appointment of a polychaete specialist, which has also encouraged overseas workers and postdoctoral researchers to study the collections, including those from Sydney Harbour.

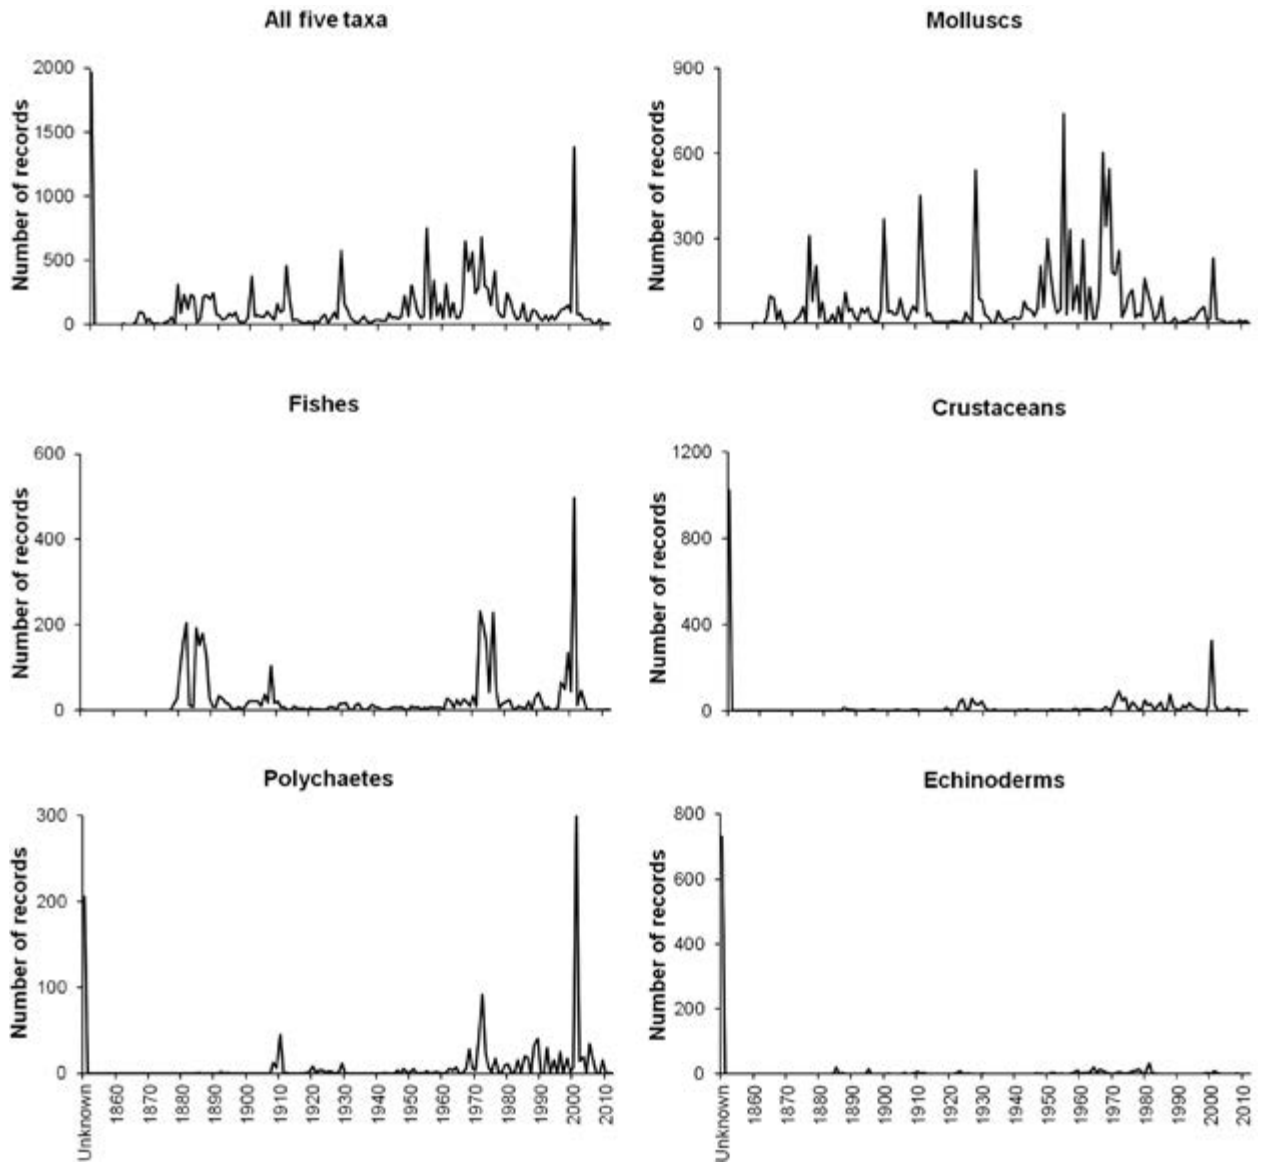

Figure 9. The number of specimens collected in each year since 1850, with unknown year of collection included separately to the left of the year 1860. Averages were used when the collection period included a range of years (e.g. 1955 for 1950–1960).

If one considers the species accumulation curve (Figure 11), it is still rising, with most species recorded from the Eastern region (i.e., east of the Sydney Harbour Bridge). Most of the species have been recorded since the 1970s coinciding with the availability of SCUBA and the museum's increased research effort. Far fewer species are recorded from the other regions although the numbers of species increased dramatically in the Central and Eastern regions following a marine biosecurity survey in which those areas associated with commercial shipping were systematically collected (Australian Museum Business Services 2002).

Polychaetes predominantly occur as infaunal and encrusting species, although some are pelagic (Figures 12-15 illustrate some common species). Comprehensive benthic sampling has not been carried out in the harbour and most records are from the intertidal and from SCUBA diving where kelp holdfasts

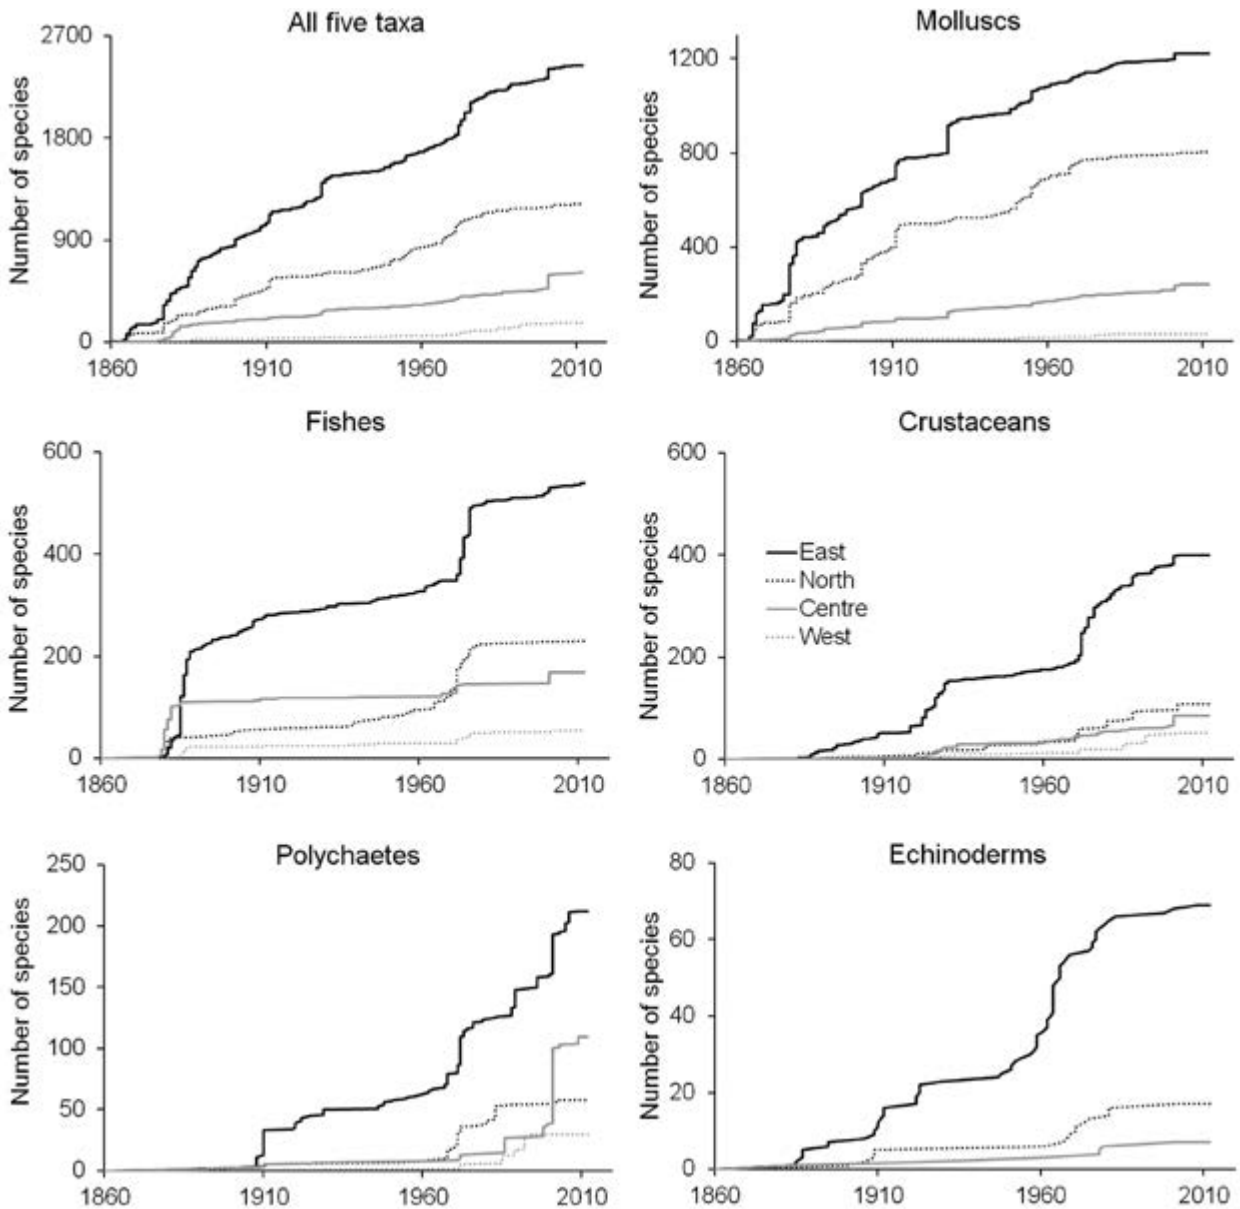

Figure 11. Cumulative numbers of species recorded in the harbour over time. Records and species without a year of collection were not included in this analysis.

and sponges are often collected to reveal associated polychaetes, plus scrapings from pylons. This suggests that many more species of polychaetes remain to be recorded from Sydney Harbour. Deeper water habitats east of the bridge, under Spit Bridge and areas inside of North and South Heads have barely been sampled. The same applies to subtidal soft sediments throughout the harbour. As our knowledge of the coastal polychaete fauna increases

Figures 16. Blue Swimmer, *Portunus armatus*, was previously known in Australia as *Portunus pelagicus*. It is an important commercial species around Australia and is common in Sydney Harbour on soft sediments, especially in the eastern region. Photo, S. Ah Yong.

Figure 17. Mantis Shrimp, *Erugosquilla grahmi*, is one of several large mantis shrimp species found in Sydney Harbour and was discovered in the mid 1990s. we would anticipate also finding many species new to science within the harbour. This is also reflected in the species accumulation curve for polychaetes (Figure 11) especially for the Eastern and Central regions that show little evidence of levelling off. In contrast, the apparent levelling off in the Northern and Western regions is possibly a sampling artefact rather than a real plateau.

Crustaceans

Crustaceans are the dominant marine arthropods and include crabs, shrimps, lobsters, isopods, amphipods and barnacles (Figures 16-18 illustrating some of the diversity). They occur throughout the harbour to the geographical limits of the study (Figure 7) and are represented by 2778 records distributed in 163 families, 434 genera, and 672 species (Figure 6, Appendix). The crustacean fauna

of the harbour is extremely rich, comprising temperate water species along with typically warm water species that are temporary residents brought by the East Australian Current, or for which Port Jackson is part of their southern range limit (Ahyong 2004; Poore 2004).

With many significant commercial species, such as School Prawns (*Metapenaeus* spp.), Blue Swimmer Crabs (*Portunus armatus*) (Figure 16), Mud Crabs (*Scylla serrata*) (Figure 18) and Eastern Rock Lobsters (*Sagmariasus verreauxi*), crustaceans in the Australian Museum collection date back to at least 1876. Growth in the Sydney Harbour crustacean collections (and the number of species discovered, as new records for the harbour or species new to science) correlates with research effort, with a peak in the 1920–30s, a peak in the 1970–80s and a spike in 2001, see Figure 9). As is evident from the species accumulation curve, the number of species discovered in Sydney Harbour

Figure 18. Mud Crab, *Scylla serrata*, is a popular commercial species that lives in muddy, mangrove habitats. It occurs widely in the tropics and occurs all along the New South Wales coast. In the harbour, it occurs mostly in the central and western regions as well as in Middle harbour. Photo, S. Ahyong.

Figures 19. Comb Sea Star, *Astropecten polyacanthus*, burrows in sand and mud, and is common around Sydney. It is one of the few echinoderms in the harbour to tolerate low salinities. Photo, S. Ahyong.

has increased across all regions in several large steps. From the 1930s to the late 1960s, crustacean discovery in the harbour was low (Figure 11), corresponding with a lack of specimens collected during this period (Figure 9). It improved significantly with the appointment of curators such as Yaldwyn and Griffin in the late 1960s early 1970s, resulting in the peak in collection records and numbers of new discoveries in the 1970–80s. The 2001 spike in records is attributable to the Sydney Harbour Biosecurity Survey conducted for the Sydney Ports Authority (Figure 10), although the limited number of new species records obtained at that time suggests that most species from the immediate port environment have already been observed.

As expected, the numbers of species recorded from different parts of the harbour differ significantly, with highest diversity in the Eastern region (Figure 8). This no doubt is partially influenced by the higher level of sampling in the east, but also the wider range of habitat types including rocky reefs and seagrass beds, and more stable marine conditions that typically favour higher species richness (Edgar *et al.* 1999; Teske and Wooldridge 2001). The Northern and more westerly regions are increasingly estuarine and more strongly affected by freshwater input (and urban runoff) than the Eastern region.

The harbour has consistently yielded new species records, even though research effort has been sporadic, especially in the past 20 years. For instance, Sydney Harbour holds the southernmost records for the tropical reef lobster, *Enoplometopus occidentalis*, the tropical mantis shrimps, *Erugosquilla woodmasoni* (Figure 17) and *Levisquilla jurichi*, and tropical swimming crab, *Charybdis granulata* (Ahyong 2001, 2006; Ahyong and Lee 2005). A large new species of mantis shrimp, *Erugosquilla grahami*, was discovered in Sydney Harbour only in 1994, among the commercial catch of prawns and other mantis shrimp, dominant among them, the introduced Japanese mantis shrimp, *Oratosquilla oratoria* (Ahyong and Manning 1998; Ahyong 2001). The species accumulation curve for Crustacea is currently plateauing and is most likely attributable to the low level of recent research effort (Figure 11). Targetted surveys in the harbour will almost certainly result in numerous new discoveries, especially in the Eastern region.

Echinoderms

Echinoderms, which include sea urchins, sea-stars and sea cucumbers, are a relatively small group with around 1200 species known from Australia. Sea urchins and sea-stars can be numerically abundant, especially on rocky reefs and other hard substrates (Figures 19–22 illustrate the diversity). For Sydney Harbour 1017 records, distributed in 45 families, 91 genera and 118 species exist in the Australian Museum collections (Figure 6, Appendix).

The growth in harbour records and consequent number of echinoderm species discovered in the harbour has substantially increased from 1860 until now (Figure 11), although the majority of old records do not have a specific collection date (Figure 9). As with Crustacea, the rate of discovery follows a step-wise pattern with the largest jump in the late 1960s. This jump follows the expansion

Figure 20. Heart Urchin, *Brissis agassizii*, is seldom seen because it generally lives below the surface of the sea-bed. It occurs widely in the Indo-Pacific, and in Sydney Harbour, is found in the eastern region. Photo, Ashley Miskelly.

Figure 21. Sand dollar, *Clypeaster australasiae*, is a sea urchin with very short spines. It occurs on sand and shelly substrates in the eastern harbour. Photo, Ashley Miskelly.

in numbers of research staff at the Australian Museum in the late 1960s and early 1970s, among them, echinoderm specialist Frank W. E. Rowe, with tenure at the Australian Museum from 1974 to 1989.

Of all groups surveyed, the echinoderms have the fewest records and species outside the Eastern region, and none in the Western region (Figures 7, 8). This pattern owes largely to the biology of echinoderms, the majority of which are poor osmoregulators that do not tolerate significantly fluctuating salinities (Diehl 1986). As such, the majority of records are from the eastern-most harbour habitats.

Molluscs

Among the taxonomic groups included in this paper, the molluscs comprise the greatest number of records (10,598), families (224), genera (725) and species (1339) (Figure 6, Appendix) (Figures 23-28 illustrate some of the diversity). This pattern follows a wider trend and these relative proportions are mirrored throughout the Australian Museum marine collections.

The mollusc collection dates from around 1860 and many of the 'peaks' seen in Figure 9 coincide with major donations. Rather than necessarily reflecting peaks in collecting activity, these spikes correspond to acquisitions of large collections or the date of the death of a collector if the specimens were acquired after that time. Often the early collectors did not record the date of collection with their specimens, so the collection dates were recorded by the museum as merely prior to the date of acquisition. Starting from the earliest to the most recent, the peaks (Figure 9) likely correspond to the following acquisitions of more than 3000 specimens that did not have exact collection dates with the specimens (some of these were former Australian Museum curators who may have acquired specimens from third parties): 1877, W. H. Hargraves collection donated; 1900, pre-1900 material from various sources; 1912, J. C. Cox collection donated; 1930, M. J. Waterhouse collection donated; 1965–1966, T. A. Garrard collection donated; late 1960s, C. F. Laceron collection donated; and in 1970, L. Woolacott collection

donated. Other peaks possibly correspond to the activities of various museum curators some of whom were more avid collectors than others, or actively identified and catalogued local species. Most recently, Winston Ponder, who became Curator of Molluscs in 1968, has contributed significantly to the museum's collections. The 2001

peak corresponds to the Sydney Harbour Biosecurity Survey conducted for the Sydney Ports Authority by the Australian Museum (Australian Museum Business Services 2002).

Reviewing the distribution of records (Figure 7) it appears that there are significant areas of the harbour that have not been sampled. The Eastern and Northern regions have the greatest number of specimen records, and, mirroring this, the greatest number of species (1201 and 788 respectively (Figure 8)). Within these zones the most extensively sampled regions are at depths of less than 10 m. This can be seen by comparing Figures 1 and 7. Some areas appear to be the targets of intensive collections of molluscs, with 301–1000 records indicated for the following locations: Middle Harbour, Manly Cove, Middle Head, Watsons Bay, Shark Bay, Berry's Bay, and off Mosman (Bradley's Head, Taylor's Bay and Chowder Bay).

The Central and Western regions have been poorly collected for molluscs and this may be due in part to difficulties obtaining access to these areas. In addition, only in recent years have Australian Museum malacologists focussed on freshwater and brackish water molluscs, which are likely to occur in the westernmost arms of the catchment area of the harbour. The paucity of specimens from these areas is reflected in the number of records (Figure 7) as well as the number of species, with 234 species recorded from the Central region and only 31 in the Western zone.

It is likely, however, that rather than reflecting collecting effort, this pattern of decreasing diversity from east to west may be real. It may relate to the decreasing diversity of habitat types and depths and fluctuating salinity, which decrease and increase respectively from east to west (see Figure 1 and Beck and Birch 2012a, b).

Figure 11 indicates that for all four regions, the number of molluscs recorded over the last 150 years is approaching a plateau. This could indicate that our knowledge of molluscan diversity in Sydney Harbour is approaching completion, or it could reflect the diminution of taxonomic research in recent years (Figure 9). Unfortunately, the decline in taxonomic research is currently a worldwide problem that urgently needs to be addressed.

Fishes

Early white settlers learned a little about the fishes of Sydney Harbour as a result of their need for food. Scientific knowledge of the ichthyofauna, however, developed slowly. In his *Voyage to Botany Bay* (1789) Arthur Phillip described a Port Jackson Shark, *Heterodontus portusjacksoni*, and a Wobbegong, *Orectolobus maculatus*, from the harbour. Since those humble beginnings, our knowledge of the fauna of Sydney Harbour has grown spasmodically (Figure 11). Castelnau's *Essay on the Ichthyology of Port Jackson* (1879) compared the fish faunas of Sydney Harbour and Victoria. More recently, Henry (1984), in his paper on commercial and recreational fishing in Sydney Harbour, stated that "The Australian Museum has recorded 581 fish species from the Sydney estuary" but did not provide a species list. The remarkably rich fish fauna is comprised of warm temperate water species and tropical species carried south in the warm East Australian Current. As of December 2011, 586 species of fishes from 391 genera and 160 families were known to occur in Sydney Harbour (Figure 6, Appendix, current figures available at <http://www.australianmuseum.net.au/Fishes-of-Sydney-Harbour>). This can be put into perspective by comparing with the 540 species known to occur in the entire Mediterranean Sea (Helfman *et al.* 2009).

The Australian Museum's earliest dated records of Sydney Harbour fishes begin in 1878, with the collection of 15 specimens (11 species), followed by 29 specimens (16 species) in 1879. In the 133 years since, four main 'spikes' in collecting activity have occurred (Figure 9). The first was between 1880 and 1890, during the tenure of Edward Pierson Ramsay (1874–1894) and James Douglas Ogilby (1884–1890). A smaller spike in collecting effort occurred in 1908, during the tenure of Allan Riverstone McCulloch (1906–1925). Over the next 60 years, minor but consistent collecting was undertaken, largely during the 42 year tenure of Gilbert Percy Whitley (1922–1964). The 1970s saw a decade of intensive collecting coinciding with the employment of John Paxton (1969–1998) and Doug Hoese (1971–2004). See Saunders (2012) and <http://www.australianmuseum.net.au/Fish-Section-Staff> for more information on the early Australian Museum ichthyologists.

The number of fish species known from the harbour has increased over time, but not steadily (Figure 11). Not surprisingly, dramatic increases in species numbers occurred during the two decades of intense collecting discussed above (1880–1890 and 1970–1980). During the first period, the number of species known from the harbour rose from 'a handful' (those recorded in early works and not retained at the Australian Museum) to over 200 that were incorporated into the Australian Museum collection. The number of known species climbed dramatically in the decade between 1970 and 1980 largely due to the efforts of Paxton who ran a seven year trawling program in the harbour, along with seining, rotenone sampling and visits to the fish market (Paxton and Collett 1975, Figure 2). The most recent spate of intensive sampling occurred around 2001 and is largely attributable to work done by the Australian Museum for the Sydney Harbour Biosecurity Survey conducted for the Sydney Ports Authority (Australian Museum Business Services 2002). During this survey, fishes were collected at 19 sites, from Chowder Bay in the Eastern region to

Blackwattle Bay in the Central region, with divers on scuba using rotenone to intensively sample the fish fauna (Figure 10). Some iconic Sydney Harbour species are shown in Figures 29–33.

During the 'wonder decade' (1970–1980), about 150 species of fishes were added to the species count, with increases in species numbers in all four regions (Figure 11). The largest increases were in the Eastern and Northern regions respectively. During this time, the number of species known from the Northern region overtook that of the Central region.

It is important to note that the two periods of greatest increase in species numbers correspond with times when Australian Museum staff members were actively pursuing programs of both research and collection in the harbour. The relatively small increase in species numbers, despite the large collection effort in 2001 may partially be accounted for by the absence of an Australian Museum ichthyologist actively working on the fauna of the harbour. Over the last two decades, the number of ichthyological

Figure 29. The Port Jackson Shark, *Heterodontus portusjacksoni*, occurs in the eastern zone. It is a distinctive blunt-headed species that has a spine in front of both dorsal fins. The 'harness-like' colour pattern distinguishes it from the similar-looking Crested Horn shark, *Heterodontus galeatus*. Photo, Sascha Schulz.

Figure 30. The Sydney Cardinalfish, *Apogon limenus*, can be recognised by the wide gap between the second and third stripes, and the short stripe running posteriorly from the top of the eye. It is a common Sydney Harbour species that is usually observed in small aggregations. The species name *limenus* comes from the Greek word *limen*, meaning 'harbour' or 'refuge'. Photo, Ian Shaw.

Figure 31. Despite its name, the Eastern Blue Groper, *Achoerodus viridis*, is not a grouper, but a wrasse. The species was made the fish emblem for New South Wales in 1996. The large, blue males commonly approach divers. Photo, Dave Harasti.

Figure 32. Eastern Red Scorpionfish, *Scorpaena jacksoniensis*, are commonly seen on rocky reefs of the outer harbour. Individuals spend much of the day motionless on the bottom. For many years, this species was incorrectly called *Scorpaena cardinalis*. The correct name, *S. jacksoniensis* (see Motomura et al. 2011), refers to the type locality of Port Jackson (Sydney Harbour). It is also known locally as the 'Red Rockcod'. Photo, Dave Harasti.

Figure 33. The distinctive Common Seadragon, *Phyllopteryx taeniolatus*, is usually seen in association with kelp-covered reefs in the outer harbour. The species is often referred to as the Weedy Seadragon, which can cause confusion with the more southerly-distributed Leafy Seadragon, *Phycodurus eques*. Photo, Sascha Schulz.

research staff at the Australian Museum has decreased from three positions (Paxton, Hoese, Leis) to one half-time position (Leis). It is unlikely that the current species count would remain static if another program of harbour-centric research was undertaken.

Despite the decline in the Australian Museum's ichthyological research capacity, the number of species known from the harbour continues to increase, often due to the work of international ichthyologists. In 2004, Australian Museum Research Associate, Hiroyuki Motomura (2004), described the Sydney Scorpionfish, *Scorpaenopsis inspiratus* (<http://www.australianmuseum.net.au/Sydney-Scorpionfish-Scorpaenopsis-insperatus>). Nearly a decade later, the holotype and paratype, both collected by staff of the Australian Museum at Clifton Gardens in the Eastern region, are the only specimens of the species that have been collected. The live colouration of the species is unknown. Another new species known from the harbour, an anglerfish (<http://www.australianmuseum.net.au/Undescribed-Anglerfish/>), is currently being described by Rachel Arnold from the University of Washington.

Many species of fishes collected from coastal areas of Sydney have not been recorded from the harbour. The outer harbour is essentially a marine environment that contains suitable habitats for many of these coastal species. Almost certainly, unrecorded coastal species occur in the Eastern region.

Many species records are based on vagrant fishes such as tropical species (e.g. butterflyfishes, cardinalfishes, damselfishes, surgeonfishes, gobies) and pelagics (e.g. billfishes, lamnid sharks, driftfishes, trevallies). Their occurrence may be based on a single record. The current paper includes 175 species (29.9%) for which the collection contains only a single specimen. It is unclear how many species are resident, how many are vagrants and how many are simply rare. An analysis of the resident fish fauna of Sydney Harbour is beyond the scope of this paper (Booth 2010).

Figure 7 clearly shows large areas of the harbour (primarily in the Northern and Western regions) in which there has been no fish collecting undertaken by the Australian Museum. If these areas are targeted, current knowledge of fish distributions will undoubtedly be improved. This point is illustrated by a single day of collecting from near Roseville Bridge, Middle Harbour (Figure 1) in May 2012 during which specimens of Blackmargin Dartfish, *Parioglossus marginalis* and Pacific Blue Eye, *Pseudomugil signifier* were collected. These were new records for the harbour and for Middle Harbour respectively. The collection of a White's Seahorse, *Hippocampus whitei* at the same locality was a notable range extension (~15 km upstream) within Middle Harbour.

A larval fish sampling program would enhance our understanding of the fish fauna of Sydney Harbour. Larvae commonly have very different habitat requirements, behaviours and food requirements to adults. Little collecting of larval fishes has been undertaken. Specimens exist from the work of Leis and colleagues who made a number of collections at Collins Flat and Quarantine Beaches (North Head) and Lockett who collected larvae from Homebush Bay and the Lane Cove River.

Discussion

This first attempt in more than a century to collate the fauna of selected groups from Sydney Harbour has revealed an amazing diversity with almost 20,000 records, 632 families, 1830 genera and 3023 species recorded. Certainly this is an underestimate of the diversity of the harbour as groups such as sponges, ascidians, bryozoans and many of the smaller groups, have not been included. As shown in Figure 8, the Eastern and Central areas have the greatest number of records for all groups excluding polychaetes. The Western area has the least. This may be due to inadequate sampling, but it is also the area with the lowest diversity of habitats and, periodically, the lowest salinities, especially after heavy rain. This would severely impact some taxa; for example, echinoderms are almost completely marine and polychaetes largely so and would not survive under these conditions. Other contributing factors may be that, historically at least, water quality was poor in this region with limited tidal flushing, and access to sampling sites is often difficult. Further east, good tidal flushing has reduced the impact of land-based pollution from harbour foreshore industries (Davis and Birch 2010, 2011). In recent decades most foreshore industries in the Western region have now been relocated with the valuable land sold off for residential development. Similar comments are also true for the Northern region (except this region has never had many shore-based industries).

The most speciose area is the Eastern region, which has more habitat types (seagrasses (Figure 34), rocky shores (Figure 35), soft substrates, pelagic habitat, is essentially an extension of the coastal marine environment. This region has been the target of the most intensive collecting effort using many techniques for all of the target groups. Interestingly, while the number of species known from the Eastern (marine) region continues to grow, the numbers from the other regions have only increased slightly over time, although for all groups the 2001 survey for Sydney Ports (Australian Museum Business Services 2002) increased the number of known species.

Figure 34. *Posidonia australis* seagrass beds toward the entrance to the harbour with Yellowfin Bream, *Acanthopagrus australis* swimming above. Photo, Dave Harasti.

With over 3000 marine species, Sydney Harbour is truly a biodiverse waterway for a combination of reasons, including a tremendous diversity of habitats, varying in types of sediment, depth, and vegetation. Seagrass beds (Figure 34) and algal beds (Figure 36) are widespread especially in the Eastern region although these deep water algal beds have not been accurately mapped. West *et al.* (2004) have undertaken a survey of the harbour based on aerial surveys of the distribution of seagrasses, mangroves (Figure 37), kelp and seagrass beds. They show that seagrass beds

Figure 35. Rocky shores opposite North Head. Photo, Penny Berents, Australian Museum.

Figure 36. The kelp *Ecklonia* from around Clarke Island at 2.5 m. Photo, Graham Edgar.

have changed substantially over the last 20 years and some subsequent maps have been produced (Creese *et al.* 2009). The same is true for mangrove communities further upstream (McLouglin 1987, 2000). Adam (1996) documented the distribution of saltmarshes around Homebush Bay and refers to the history of saltmarsh reclamation and modification in this region (Clarke and Benson 1988; Kachka 1992) (Figures 38-40). Inside Sydney Heads are extensive sponge gardens that are home to diverse communities of invertebrates and fishes (Hutchings pers. observ. Figure 41). Also inside the heads are extensive sea-urchin barrens (Figure 43). Many intertidal habitats have been substantially changed since European settlement with reclamation for buildings, seawalls, port and marina facilities, replacing

Figure 40. Homebush Bay reclamation from 1900–1988, Prepared for Homebush Bay Corporation

complex substrates and habitat with large areas of uniform, hard surfaces (Glasby and Connell, 1999) (Figure 42). Mangrove coverage has also changed over time (McLoughlin 2000 and refs therein; West *et al.* 2004; Creese *et al.* 2009), but significant stands are still present in the Northern and Western regions (Melville *et al.* 2005). Sydney Harbour, is a natural harbour and has experienced relatively little dredging except around in areas such as Circular Quay and Darling Harbour and further upstream around Homebush Bay associated with salt ponds and later industry (Clarke and Benson 1988; Fox and Associates 1986).

The largest number of records from the harbour are of molluscs. But, does this pattern in Sydney Harbour reflect collection effort (as measured by the number of records) and research focus, or are molluscs really the most diverse marine group in Sydney Harbour? Do historical factors need to be considered?

The Australian Museum mollusc collection differs in some important respects from the other collections covered in this report. Because of its vast size, only about one-third of the entire mollusc collection is presently databased, so the statistics regarding the mollusc records from Sydney Harbour must be considered preliminary. Of these records, however, a higher proportion of local species (i.e., from the Sydney area and environs) rather than distant or non-Australian material is databased. Another significant difference is that, unlike the other groups treated here, molluscs are a major target group for amateur collectors, who have been the source of many specimens in the Australian Museum collection, especially in the early years (Hope Black 1998). These collections have come to the Museum periodically, either purchased or donated, often with only approximate or no information on the dates of collection and sometimes dubious locality information and identifications. Little emphasis was placed on accurate recording of data up to the mid 20th century. Because the early records are largely comprised of information from donated collections, they tend to be less reliable than data obtained from more recent collections.

Another peculiar complication for the malacology collection is determining the status of specimens collected as empty shells. If empty shells were collected from a locality at which the same species is currently living, it is reasonable to assume that the shells are recent. In the absence of living individuals, however, an assessment is made on the state of the shell and its microhabitat to determine whether the shell is recent. A fresh-looking

Figure 43. Urchin Barrens occur all around North and South Head, Quarantine Bay and at several locations in the harbour such as the reef around Chowder Bay and Middle Head, at depths of 2 m to 20 metres. Photo, Dave Harasti.

shiny shell is usually modern, but some subfossils can have a remarkably 'fresh' appearance. If a shell came from deep dredging, from well below the substrate surface, it could be a subfossil, and then geological evidence is required to estimate its age. In ascertaining species distributions, fossil shells add a significant time dimension that needs to be considered. Mollusc species numbers may be overinflated by the inclusion of fossil molluscs — the listed species will probably include some that no longer occur in the harbour but may have occurred there at some time in the geological past.

Also, for all the groups considered in this paper, additional species may be present in other collection databases but checking these was beyond the scope of this paper. We know for example that a paratype of *Oxycheilinus nigromarginatus*, the Blackmargin Maori Wrasse (<http://www.australianmuseum.net.au/Blackmargin-Maori-Wrasse-Oxycheilinus-nigromarginatus/>), from Camp Cove (Eastern region) is held in the collection at Museum Victoria (A 11834). No specimens of this species from the harbour are currently in the Australian Museum collection.

For all the invertebrate groups, additional collecting, especially in deeper parts of the harbour and in soft sediments, will undoubtedly result in the discovery of additional species and records. An area which has been very poorly sampled is upstream from Spit Bridge which covers approximately 4.7 km², and represents 9.1% of the total harbour and while molluscs are reasonably well sampled in this area (~9.3% of all records), other groups are not (1.0% polychaetes, 1.7% fish, and 3.8% crustaceans, with virtually no echinoderms but this is to be expected) (Figure 7), certainly targeted surveys in this region would no doubt increase the known diversity of the harbour.

In addition, among the invertebrate groups there are collections of unstudied material that remain to be

identified and databased; these will no doubt include additional records and new species. Also, as seen in Appendix, some records are yet to be identified to species level, and this in part reflects taxonomic limitations.

Considering that Australia's largest city surrounds the harbour, it is remarkable that we have such a diverse fauna. However, we have not yet determined how many records of species have not been found in the past 10–20 years. Even if we did so, it would be difficult to know whether they have actually been lost from the harbour or whether their habitats have simply not been sampled recently. In no small part, the diversity found in the harbour is due to its geomorphology and the wide deep entrance that greatly facilitates water exchange and recruitment from nearby areas. Without this water exchange, salinity would be much less stable and water quality would have been seriously compromised, especially in the late 1800s early 1900s when sewage remained untreated and a whaling station operated at Mosman.

Comparisons with neighbouring estuarine areas are instructive. To date, the total number of polychaete, crustacean and mollusc species recorded from Sydney Harbour stands at 2319, although these numbers are certainly a significant underestimate of true species richness since many areas of the harbour are poorly sampled. This compares with 1636, 1335 and 981 species known from the nearby (<30 km) estuaries Botany Bay, the Hawkesbury River and Port Hacking, respectively, based on Australian Museum collection records (Hutchings and Murray 1984; Wilson 1998; Fraser *et al.* 2006). Each of these areas is smaller and has far fewer types of habitat than Sydney Harbour, highlighting the environmental significance of the harbour.

Sydney Harbour is clearly a highly diverse environment in which much remains to be discovered. The present study highlights the remarkable species richness of Sydney Harbour.

Acknowledgements

We would like to thank Ian Loch and Des Beechey who provided historical information regarding the Malacology collection. Patricia Egan provided us with images from the Australian Museum archives and Fiona Simpson and Emma Gray of the library at the Australian Museum also helped us with tracking down early literature. Michael Elliot manipulated the data base for us. The bathymetry of Sydney harbour was kindly supplied by Phil Mulhearn of Sydney University based on the soundings of Roads and Maritime Services. John Paxton is acknowledged for his comments on fish collecting during the 1970s. Amanda Hay and Sally

Reader have worked for years improving the accuracy of fish database records. Alex Hegedus assisted with locating early historical records of marine invertebrates. Winston Ponder checked for introduced mollusc species. We also thank the valuable comments made by the two reviewers and the editor. Finally we would like to thank all the following photographers who have allowed us to reproduce their photos. They are acknowledged by name in the figure captions. John Hooper is thanked for identifying the sponges for us.

This is contribution 78 from the Sydney Institute of Marine Science.

APPENDIX 2

This unusual painting of the early 19th century shows a highly creative arrangement of freshly caught fishes - some are lying on the sand, while others appear to be floating as if they are still in the waters of Sydney Harbour (visible in the background). Most of the fishes portrayed in their relative sizes were common to the Sydney Harbour waters almost 200 years ago but the largest fish is one of the freshwater cods and is unlikely to have been caught in the harbour. The fishes include (from the top) snapper; hammerhead shark; redfish; freshwater cod; Southern maori wrasse; whiting and sea mullet. Painted in oils by Australia's first professional artist, John Lewin (1770-1819), the work measures 86.5 cm x 113.0 cm. It depicts a site that today has iconic status within Australia - the fish are arranged on the shore at Kirribilli Point; the view behind the fish stretches south across Sydney Harbour to Dawes Point, where the southern end of the Sydney Harbour Bridge is now located; in the distance, the hip-roofed guardhouse and flagpole of the former Dawes Point Battery can also be seen. Postcard no. 00086 © Copyright of the Art Gallery Board of South Australia 1993 (original painting held in the Art Gallery of south Australia).
